ABSTRACT

Finding a named person in broadcast news video is important to video retrieval. Relying on the text information such as video transcript and OCR text, this task suffers from the temporal mismatch between a person's visual appearance and his/her name occurred in text. By exploring video grammar on the concurrence pattern between faces and names, we propose an extended text-based IR method to overcome this problem and yield superior performance.

H.3.3 [Information Storage and Retrieval]: Information Search and Retrieval - *Retrieval model*

General Terms

Algorithms, Experimentations

Keywords

Video retrieval, concurrence pattern, video grammar

1. INTRODUCTION

Large volumes of digital videos make effective and efficient access to video content an imperative task for the digital library community. One important research issue is to find the visual appearances of a named person in the video [1], especially in broadcast news videos which are mainly about people. This can be facilitated by video transcript and video OCR text (VOCR), but their usefulness is compromised by the fact that people do not always temporally co-occur with their names. We attack this problem by exploring an aspect of video grammars, namely the concurrence pattern between people's faces and their names, to reformulate the text-based IR model which achieves more accurate people finding. Variations of our approach are discussed and their performance compared with experiments on the TREC Video Track data[2], which are divided into a training set (FSD) and a testing set (FST), each consisting of 100+ hours of ABC and CNN news video.

2. CONCURRENCE PATTERN

A clue for finding a specific person in news video is his/her name in the accompanying text (transcript or VOCR). This indicates that a person is likely to show up in close proximity. The search is conducted at the shot level, i.e., finding all video shots that contain the intended person. Transcript or VOCR text are temporally

aligned with the video, and thus each shot is associated with the text that falls within its boundary. To find a specific person, we can treat each shot as a text document and use his/her name as a query to find the shots containing the name using vector model based text retrieval. However, this method is compromised by the observation that, in more than half the cases, a person does not appear in the shot where the name is mentioned, but before or after that shot. Obviously, such mismatches degrade the performance.

The timing between a person's faces and his/her names is related to the *video grammar* of broadcast news, i.e., the style and structure typical of a certain genre of video. A news story starts with an anchor briefing the story, followed by several shots showing the news event. The name of a news subject is normally mentioned by the anchor, but his/her face is often not shown at that time. In the following shots, this person may appear several times in the video, interleaved with his/her name occurred in the text. Sometimes a person not mentioned by the anchor later appears. This grammar is different depending on text source (transcript vs. VOCR), channel (ABC vs. CNN), target person, etc. Generally, a person appears in the close proximity of where his/her name is mentioned.

Figure 1: The frequency of Bill Gates' faces w.r.t to his name

The video grammar results in what we called *concurrence pattern*, which models the probability that a person appears in a shot at a certain distance from his/her name. To illustrate this pattern, we labeled all the faces of "Bill Gates" in FSD, and plot in Fig.1 the frequency of his face appearing at each quantized distance from the closest name. "0" on the distance axis is where the name is mentioned, and positive distance means he appears after his name. Based on Fig.1, it is intuitive to model the frequency of a person's visual appearance w.r.t his name by a Gaussian model. For a specific person, we can estimate a Gaussian distribution from the distances from each of his face in FSD to the *closest* name in transcript or VOCR using maximum likelihood estimation. We superimpose the curves of the estimated distribution for "Bill Gates" in Fig.1, which nicely captures the shape of the bins of frequency.

3. THE PEOPLE-FINDING METHOD

Given the concurrence pattern, the mismatch of the text retrieval can be overcome by propagating similarity scores from the shots containing the name to the neighboring shots. Thus, the probability that a person named X appears in shot S is computed as:

$$P(X, S) = \sum_{|S-S_i| < w} f(S, S_i) R(X, S_i) \quad \text{and} \quad f(S, S_i) = \int_{start(S)}^{end(S)} N(u, \sigma^2)$$

where S_i denotes a shot having the intended name X and is within a window of size $2w$ around S , and $R(X, S_i)$ is the similarity score between S_i and name X computed from text retrieval. $f(S, S_i)$ is a weighting function calculated from a Gaussian distribution $N(u, \sigma^2)$ that models the concurrence pattern.

The concurrence pattern depends on many factors, such as:

- *Transcript vs. VOCR*: It is reasonable to assume that the concurrence pattern for transcript is different from that for VOCR. When a name appears in VOCR (i.e., overlaid text), most likely the person is also being shown, which is not necessarily true for transcript. Thus, we need to train separate distributions for transcript and for VOCR to handle different types of text.
- *CNN vs. ABC*: Editors of the two TV channels may have distinct styles in editing the news video, resulting in different concurrence patterns. If the discrepancy is large, using separate distributions for the two channels will be beneficial.
- *Local or global distribution*: We can train local distributions on a per-person basis and use each of them for a specific person, or we can train a global distribution using all the training data. If each person has a unique distribution, and there is sufficient training data for them, we prefer to use local distributions.

4. EXPERIMENT AND DISCUSSION

20 persons are selected for testing, varying from frequent ones like "Michael Jordan" to rare ones like "Alan Greenspan". Fig.2 shows the mean and standard deviation of the Gaussian distributions of each person and of some global distributions, each labeled with a name and the number of training data used. The first 4 items on the left are the global distribution of video transcript (*Trans*), transcript in ABC (*Trans_ABC*) and CNN (*Trans_CNN*), and VOCR (*VOCR*). On average, a person appears 1.8 seconds after his/her name is mentioned. The length of the delay is different for ABC (2.2 sec) and CNN (1.5 sec), showing a difference in the editing style. VOCR has a smaller delay mean than that of transcript, which implies that names in VOCR are stronger indicators of the appearance of people. The per-person distributions are ordered in descending number of training data used. The distributions for the first 9 people (with 20+ training data) are relatively similar to each other and have small variances, while those for the other people (with fewer training data) differ significantly. But it is premature to say that each "infrequent" person has a unique distribution, since our observation is biased by the limited training data.

Figure 2: Gaussian distributions estimated from FSD

In the experiment, each variation of the proposed method is used to find the 20 people in FST and evaluated using average MAP

(mean average precision). We divide the experiments into 4 groups, each examining a specific design option while the others are fixed, as shown by different colors in Fig.3.

Figure 3: Performance comparison

- In Group 1, both using transcript, our method based on global distribution (*Trans_Global*) achieves over twice the performance of the baseline method (*Baseline*), which does not consider the concurrence pattern. This suggests that the concurrence pattern is very helpful in people-finding.
- Group 2 examines whether using two specific distribution for ABC and CNN (*Trans_Channel*) is superior to using a uniform one. As we can see, although the improvement is small (about 1%), using separate distributions does help.
- Group 3 shows that VOCR (*VOCR_Global*) is not as useful as transcripts, because many names seldom occur in VOCR. Based on the statistics, the name occurrences in VOCR are only 10% of that in transcripts, echoing the difference in performance. Combing their results using logistic regression (*Text_Global*), we improve the transcript-based search by 2%, implying that these two types of text are complementary.
- Group 4 investigates the use of local distributions (*Trans_Local*) estimated on a per-person basis, which is not as good as the global distribution. By looking into the MAP for each query (person), we find that the performance suffers on infrequently appearing people, while for frequent people the choice of distribution almost makes no difference.

5. CONCLUSION

This paper addresses finding named persons in broadcast news video based on transcript and video OCR. As an aspect of video grammars, the concurrence pattern between people's faces and names is studied and modeled using Gaussian distribution. An extended text-based IR method is proposed for people-finding, and experiments have validated the performance of this method.
